ACKNOWLEDGMENTS

I gratefully acknowledge the advice and unending patience of my major advisor, Brian Bowen, and my committee members Karen Bjorndal and Mark Brenner. For enduring long hours and many insect bites on the beach, I thank D. Bagley, C. Coogan, K. Diemer, E. Dunlavey, L. Ehrhart, L. Fisher, J. Foote, M. Godfrey, L. Iocco, M. Lamont, B. Liebert, K. Moore, L. Parris, N. Price, R. Reardon and C. Vietas. For assistance in the lab, I recognize the extensive contributions of Shaio-Mei Chow and Anna Bass. Amy Ball and Michelle Zatcoff answered all my data analysis questions. Writing would not have been finished without the help (and imposed deadlines) of Joel Carlin and Steve Johnson. I am grateful to Dale Johnson for drafting all the figures and for giving me a place to stay. For invaluable contributions to the project I thank E. Almira, J.C. Avise, J. Beam, A. Bolton, R. Carthy, P. Castaneda, S.E. Encalada, A. Foley, S. Hopkins-Murphy, J.A. Huff, S.A. Karl, R.C. Klinger, A.B. Meylan, R. Mezich, N. Mrsovsky, L. Ogren, F. Percival, E. Possardt, J.I. Richardson, C.J. Sears, S. Shanker, B. Schroeder, W. Witzell, M. Zacks-Karl, and J.C. Zurita. I extend special thanks to Shirley Reynolds and the Volusia County Turtle Patrol. For logistic support I gratefully recognize Broward County Environmental Quality Control Board, the Florida Department of Natural Resources, Florida Cooperative Fish and Wildlife Research Unit, the DNA Sequencing Core at the University of Florida, and the

U.S. National Park Service. This research was funded by the National Marine Fisheries Service, the U.S. Fish and Wildlife Service, The Turner Foundation, and private contributions. My parents, Donna and David Francisco, provided moral support and kept me clothed throughout my lengthy college career. I especially thank my husband, Jeff, for believing in me and for understanding the role of the president and the elephant shoe.

CONTRASTING POPULATION STRUCTURE OF THE
LOGGERHEAD TURTLE (*CARETTA CARETTA*)
USING MITOCHONDRIAL AND NUCLEAR
DNA MARKERS

By

Alicia Francisco Pearce

May 2001

Chairman: Brian Bowen

Major Department: Department of Fisheries and Aquatic Sciences

Mitochondrial DNA (mtDNA) and microsatellite DNA (nuclear DNA, nDNA) analyses were applied to loggerhead turtles (*Caretta caretta*) in the Northwest Atlantic to determine geographic boundaries of breeding aggregations, elucidate male migratory behavior and assess stock structure. The geographic boundaries of nesting aggregations were determined by analysis of 12 nesting beaches throughout Florida using maternally inherited mtDNA. Overall we observed strong population structure among nesting beaches ($\Phi_{ST}=0.298$), but adjacent beaches were not significantly different with one exception; the offshore islands of the Dry Tortugas. Nesting site fidelity appears to operate on a scale of 100 km rather than individual beaches, consistent with the level of relocation observed in tagging studies. Genetic signatures of male migratory behavior and genetic

stock structure were analyzed using biparentally inherited nDNA applied to the 12 Florida beaches and specimens from nesting beaches in Georgia, South Carolina, North Carolina, and Brazil. The overall population structure among nesting beaches at the nDNA level was low ($F_{ST}=0.0187$), an order of magnitude lower than the structure found with mtDNA. Because of different inheritance dynamics of mtDNA and nDNA, these results are not conflicting, but rather show that males either are not philopatric or (more likely) they mate opportunistically during migration.

CHAPTER 1 OVERVIEW

Loggerhead turtles, *Caretta caretta*, are in the family Cheloniidae that includes five other extant species of sea turtle. Loggerheads occur around the world in temperate, tropical, and subtropical waters of the Atlantic, Pacific, and Indian Oceans. Unlike other species of sea turtle, major loggerhead nesting aggregations are generally located in warm temperate and subtropical regions except for one of the larger rookeries on Masirah Island, Oman (Dodd 1988). The U.S. hosts what is perhaps the largest nesting concentration with more than 14,000 females nesting each year from North Carolina through the Gulf Coast of Florida (Meylan et al. 1995, Ehrhart 1989, Murphy and Hopkins 1984).

Sea turtles spend their life at sea with the exception of mature females that trudge up beaches to lay eggs 2-7 times a nesting season (Dodd 1988). Females reach sexual maturity at 20-30 years of age and nest approximately every 2-3 years (Klinger and Musick, 1995, Frazer and Ehrhart, 1985). Since loggerheads spend so little time on land, most of our knowledge of sea turtle migration has come from tag-recapture studies. Tags placed on nesting females revealed that many turtles returned to the same beaches in successive years, which led to several hypotheses about the apparent nest site fidelity of sea turtles. The two most prominent were "social facilitation" and "natal homing". The social facilitation model proposed that first time nesters follow experienced females from foraging grounds to nesting beaches and imprint on that beach for

subsequent reproductive efforts (Owens et al. 1982). The natal homing theory proposes that hatchlings imprinted on their natal beaches and return to these beaches to reproduce. A direct test of these alternatives would be prohibitive, requiring thousands of hatchlings each with a tag that would persist from hatchling to adult (20-30 years). Hence a new approach was necessary to discover how females choose nesting beaches.

With the invention of polymerase chain reaction (PCR), studies involving maternally inherited mitochondrial (mt)DNA became possible and could be used to discern which hypothesis about nest site fidelity explains marine turtle behavior. If social facilitation occurs, there would be no genetic structure among regional nesting beaches, while natal homing would mandate genetic partitioning among beaches. Studies of mtDNA support natal homing in nesting green (*Chelonia mydas*, Norman et al. 1994; Encalada et al. 1996), loggerhead (Bowen et al. 1994, Encalada et al. 1998), and hawksbill turtles (*Eretmochelys imbricata*, Bass et al. 1996). Although mtDNA assays have revealed much about sea turtle life history and behavior of females, precise geographic boundaries of breeding aggregations as well as male migratory patterns and possible philopatry remain largely unknown.

Habitat destruction, commercial fisheries, and pollution have adversely affected marine turtle species worldwide. The predictability of sea turtle nesting seasons paired with the relative ease of capturing females on land has drastically reduced population sizes due to the slaughter of nesting females and collection of their eggs. Turtles are also vulnerable in the marine environment, being killed

both intentionally and incidentally by trawl, gill net, pound net, and longline fisheries. Consequently, loggerhead turtles are listed as threatened under the U.S. Endangered Species Act of 1973 and are restricted from international trade by CITES. The National Marine Fisheries Service and the U.S. Fish and Wildlife Service (1991) have formulated a recovery plan for loggerheads that outlines the need to 'define geographical boundaries of breeding aggregations' and to 'determine movements and distribution of adult males'.

To address the questions about the geographic boundaries of breeding aggregations and movements and distribution of adult males, mtDNA and microsatellite DNA (nuclear DNA) analyses were applied to loggerhead turtles in the Northwest Atlantic. The geographic boundaries of nesting aggregations were examined in an analysis of 12 nesting beaches throughout Florida using maternally inherited mtDNA. Genetic signatures of male migratory behavior and genetic stock structure were analyzed with biparentally inherited microsatellite DNA applied to the 12 Florida beaches and specimens from nesting beaches in Georgia, South Carolina, North Carolina, and Brazil.

CHAPTER 2
STOCK STRUCTURE AND NESTING SITE FIDELITY IN FLORIDA
LOGGERHEAD TURTLES (*CARETTA CARETTA*) RESOLVED WITH MTDNA
SEQUENCES

Introduction

The loggerhead (*Caretta caretta*) is the only marine turtle that nests primarily outside the tropics. Major nesting aggregates exist in warm temperate regions of the Atlantic, Indian, and West Pacific Oceans but are absent from the central and eastern Pacific. Despite this wide distribution, there are few large (>10,000) nesting aggregations of loggerheads. The southeastern United States from North Carolina to Florida probably encompasses the largest loggerhead nesting aggregation in the world, hosting 35-40% of the total loggerhead nesting effort (Bjorndal et al. 1983, Meylan et al. 1995). Within this region, Florida accounts for 90% of the nests, making this state a critical habitat for nesting loggerheads.

After reaching sexual maturity at an estimated 20-30 years of age (Bjorndal et al. 2000, Klinger and Musick 1995; Frazer and Ehrhart 1985), female loggerheads nest every 2-3 years on average (Bjorndal et al. 1983). Tagging studies demonstrate that females tend to return to the same beaches to nest and utilize the same foraging grounds between nesting seasons (Limpus et al. 1992). This observation prompted Carr (1967) to suggest that females are returning to their natal beach. A testable corollary of this natal homing hypothesis is genetic

partitioning between nesting areas, an expectation that has been confirmed in several sea turtle species (Bowen and Karl 1996). In particular, Bowen et al. (1993) found evidence of natal homing for loggerhead turtles in the southeastern U.S. using maternally-inherited mitochondrial DNA (mtDNA).

Encalada et al. (1998) surveyed mtDNA control region variation in ten major nesting areas in the Atlantic Ocean and Mediterranean Sea. Although sharing of haplotypes between geographic regions was observed, most nesting aggregates were genetically distinct populations. The distribution of mtDNA markers resulted in the delineation of (at least) six population genetic units, including three in the southeastern United States: (1) North Carolina, South Carolina, Georgia and northeast Florida (Atlantic coast), (2) south Florida, and (3) northwest Florida (Gulf of Mexico).

There were several gaps in coverage of nesting beaches surveyed by Encalada et al. (1998), especially in Florida where the majority of nesting occurs. Low sample size was a factor that may have limited statistical power to detect partitions among distinct nesting aggregates because, for example, this study included only six specimens from Melbourne, the center of the largest nesting aggregate (Meylan et al. 1995). As a result, the genetic assays were sufficient to show regional differentiation, but could not precisely define the boundaries of (genetically distinct) nesting populations. Therefore, a primary motivation of this study was to resolve the geographic limits of nesting populations, as defined by the nesting site fidelity of female loggerheads. Schroth et al. (1996) reported evidence of population structure on a scale of 100 kilometers in the

Mediterranean. In contrast, nesting aggregates in North Carolina, South Carolina, and Georgia U.S.A. separated by hundreds of km of coastline, are monotypic in terms of mtDNA control region sequences, indicating very close relationships and no detectable population structure (Encalada et al. 1998). FitzSimmons et al. (1996) demonstrated population structure between nesting colonies in eastern and western Australia, but low detected variation precluded a more detailed analysis. Hence the geographic limits of nesting populations remain controversial.

To accomplish the genetic test of nesting site fidelity, we conducted a survey of mtDNA sequence diversity throughout the Florida peninsula, including 12 locations with samples sufficient for population-level analyses. In addition to the 101 Florida samples analyzed by Encalada et al. (1998) we sampled more beaches and increased sample sizes for some of the larger nesting aggregates (N=274). The Dry Tortugas was also sampled since these islands lay on the outer fringes of the Florida peninsula.

To conduct a hierarchical analysis of genetic variance, nesting beach samples were divided into the four zones previously defined by management personnel (Meylan et al. 1995): northeast Florida, southeast Florida, southwest Florida, and northwest Florida (the panhandle) (Fig. 1). We chose these zones as an objective starting point for evaluating hypotheses about geographic subdivisions because they are approximately concordant with biogeographic boundaries (see Fig. 1 legend). The larger sample size allowed us to conduct an

analysis of molecular variance to determine if the zones correspond to a hierarchical structure of genetic diversity.

This research has several implications for loggerhead biogeography and natural history, but it is also relevant to the conservation of this threatened species. Since loggerhead turtles have natal homing behavior, a decimated nesting population in one area may not be replenished by turtles from other areas. Distinguishing the number and size of nesting populations, and the precision of natal homing, are necessary prerequisites for informed management decisions.

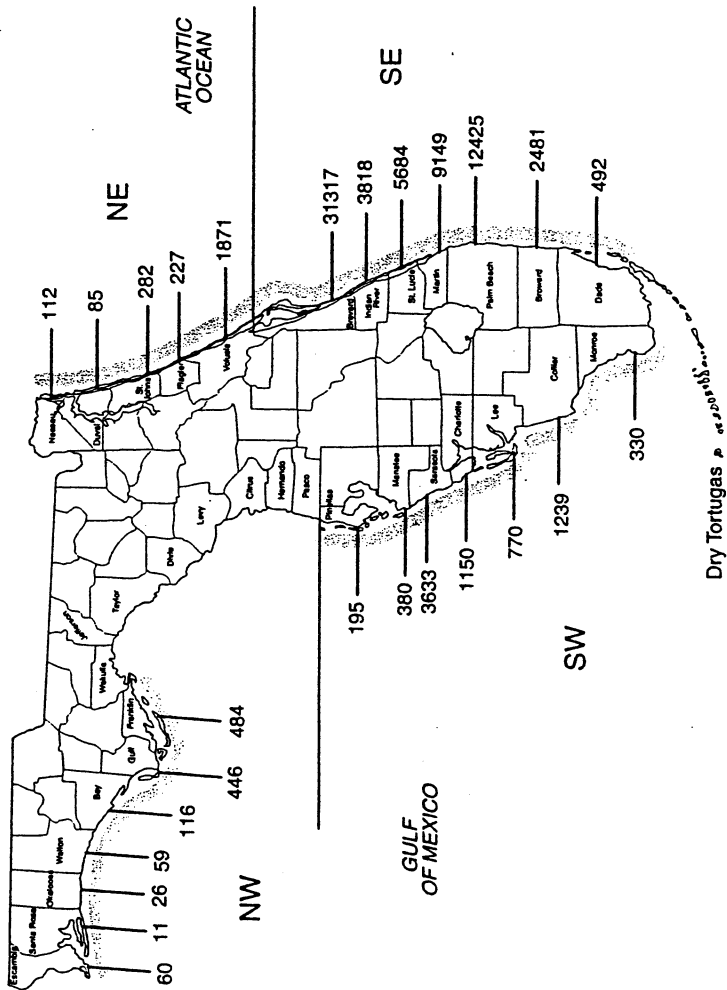

Figure 1. Management zones of Florida and number of nests per year averaged over the last three years for each county (www.fmri.usf.edu/turtle/nesting/default.htm). These four zones are separated by recognized marine biogeographic barriers. In the case of NE vs. SE, and NW vs. SW, management zones are separated by biogeographic boundaries between temperate and subtropical zones with borders at Cape Canaveral and Tampa Bay (Briggs 1974, Aulsebrook 1992). The division between SE and SW is the freshwater outflow of the Everglades as such outflows are recognized distribution breaks for coastal marine organisms (Muss et al. 2001). However, the distribution of loggerhead nesting straddles the Cape Canaveral boundary and possibly the Everglades boundary such that biogeographic zones defined for other marine organisms may not strictly apply to marine turtles (see discussion).

Materials and Methods

Sample Collection

Samples from 173 nesting females were obtained between 1995 and 1999 from four regions of Florida: 1) northeast Florida (NEFL): Volusia County (VC, n=49); 2) southeast Florida (SEFL): Melbourne Beach (MB, n=40); 3) southwest Florida (SWFL): Dry Tortugas (DT, n=58), Sarasota County (SC, n=19); and 4) northwest Florida (NWFL): Cape San Blas (CSB, n=7). Tissue from moribund hatchlings, embryos, and skin biopsy punches were placed in 15 mL of a saturated salt (NaCl) buffer (Amos and Hoelzel, 1991) and stored at room temperature. Blood samples were obtained from the dorsal cervical sinus of nesting females following the procedure of Owens and Ruiz (1980) with 1 mL of blood placed in 9 mL of lysis buffer (Fitzsimmons et al. 1999) and stored at room temperature. Precautions were taken to ensure that individual females were sampled only once. These precautions included 1) tagging the sampled females, and 2) sampling within the 11-15 day renesting interval. Females may nest several times in a nesting season, but rarely at intervals shorter than 11 days; (Dodd 1988).

These samples are added to the data from 101 Florida nesters previously analyzed by Encalada et al. (1998). Locations previously sampled were 1) NEFL: Amelia Island (AI, n=12); 2) SEFL: Melbourne Beach (MB, n=6), Hutchinson Island (HI, n=9) and Port Everglades (PE, n=10); 3) SWFL: Key

Island (KI, n=15) and Sarasota County (SC, n=10); and 4) NWFL: Eglin Air Force Base (EAFB, n=21), Tyndall Beach (TB, n=7), and St. Joseph (SJ, n=11).

Data Collection

Whole genomic DNA from tissue and blood samples was isolated using phenol/chloroform extractions followed by ethanol precipitation (Hillis et al. 1996). A 391 base-pair (bp) fragment located in the control region of the mitochondrial genome was amplified with polymerase chain reaction (PCR) methodology (Mullis and Faloona 1987), using the primers CR-1 (5'-TTG TAC ATC TAC TTA TTT ACC AC-3') and CR-2 (5'-GTA CGT ACA AGT AAA ACT ACC GTA TGC C-3') (Norman et al. 1994). The annealing temperature was 52°C with 1.5 mM MgCl₂ in 50 µl volume reactions. All PCR amplifications contained a negative control (DNA free) reaction to guard against contamination. PCR products were purified using 30,000 MW filter units (Millipore, Inc.). Cycle sequencing reactions were conducted with Big Dye technology (ABI Inc.), and fragments were gel separated at the University of Florida DNA Sequencing Core using an automated sequencer (373A and 377, ABI). Chromatograms were checked against computer base calls to ensure accuracy and then aligned using Sequencher 3.1. These sequences were compared to previously identified haplotypes from nesting and foraging locations (Encalada et al. 1998, unpublished data) and were assigned corresponding haplotype letter designations.

Data Analysis

The distribution of sequence variation among populations was determined using ARLEQUIN ver. 1.1 (Schneider et al. 1997) which correlates genotype distances at various hierarchical levels with Φ -statistics. For the purposes of this study, Φ_{ST} measures the proportion of genetic diversity within a nesting beach relative to the entire data set. Φ_{CT} is the proportion of genetic diversity within the four management regions defined above relative to the entire data set, and measures the proportion of genetic variation among groupings of nesting beaches. Φ_{SC} measures the proportion of variation among nesting beaches within a region. The significance of Φ -statistics was assessed by comparison to values generated from 1023 random permutations of sequences among populations. The groupings used for the hierarchical AMOVA included variations on the classification scheme defined by management personnel (NE, SE, SW, NW; Meylan et al. 1995), such as including the Dry Tortugas in the SW group, treating the Dry Tortugas as a separate entity, and combining the SE and SW zones because they were not significantly different in some analyses (see legend Table 3).

The amount of sequence variation within nesting populations was summarized as haplotype diversity (h) and nucleotide diversity (π , the average number of pairwise nucleotide differences per site; Nei 1987) calculated with ARLEQUIN. Genetic heterogeneity among nesting beaches was also assessed by chi-square tests of haplotype frequencies. Values were compared to distributions obtained by randomizing individuals among populations using Monte-Carlo resampling (Rolf & Bentzen 1989), as implemented in CHIRXC

(Zaykin and Pudovkin 1993). Estimates of migration (N_m , number of migrants between nesting beaches per generation) were calculated based on Φ_{ST} estimates using the equation $N_m = [1 - \Phi_{ST}] / [2 \Phi_{ST}]$.

Results

A 380 bp fragment of the mtDNA control region (removing 11 ambiguous bp at the ends of the 391 bp fragment) was aligned for all sequences. Eleven haplotypes were present among the 274 sequences analyzed (Table 1). All of the haplotypes correspond to previously reported sequences from *C. caretta*, but two of the haplotypes (K and M) were previously observed in specimens from foraging grounds (Bolten et al. 1998, Laurent et al. 1998), and haplotype CC20 had been observed only in a turtle stranded in Georgia (unpublished data).

Nucleotide diversity within populations was high ($\pi = 0.022 \pm 0.011$), as was the nucleotide diversity for all populations together ($\pi = 0.032 \pm .016$). This was due to the presence of two phylogenetically distinct clusters of haplotypes (Encalada et al. 1998). The average value for within population haplotype diversity was high ($h = 0.460$) and ranged from 0.000 to 0.714 (Table 1).

Haplotypes A and B accounted for 91.6% of the individuals sampled, but the distribution of these two haplotypes was not uniform across Florida (Fig. 2). For example, haplotype B was present in 21% of the turtles in NEFL, 40% in SEFL, 65% in SWFL and 15% in NWFL. Haplotype A shows the opposite trend, occurring 72% of the time in NEFL, 53% in SEFL, 24% in SWFL, and 78% in NWFL.

Table 1. Distribution of mtDNA haplotypes for Florida loggerheads and within-nesting beach haplotype diversity (h) and nucleotide diversity (π). Top row contains original haplotype designations, with haplotype designations according to Laurent et al. (1998) below.

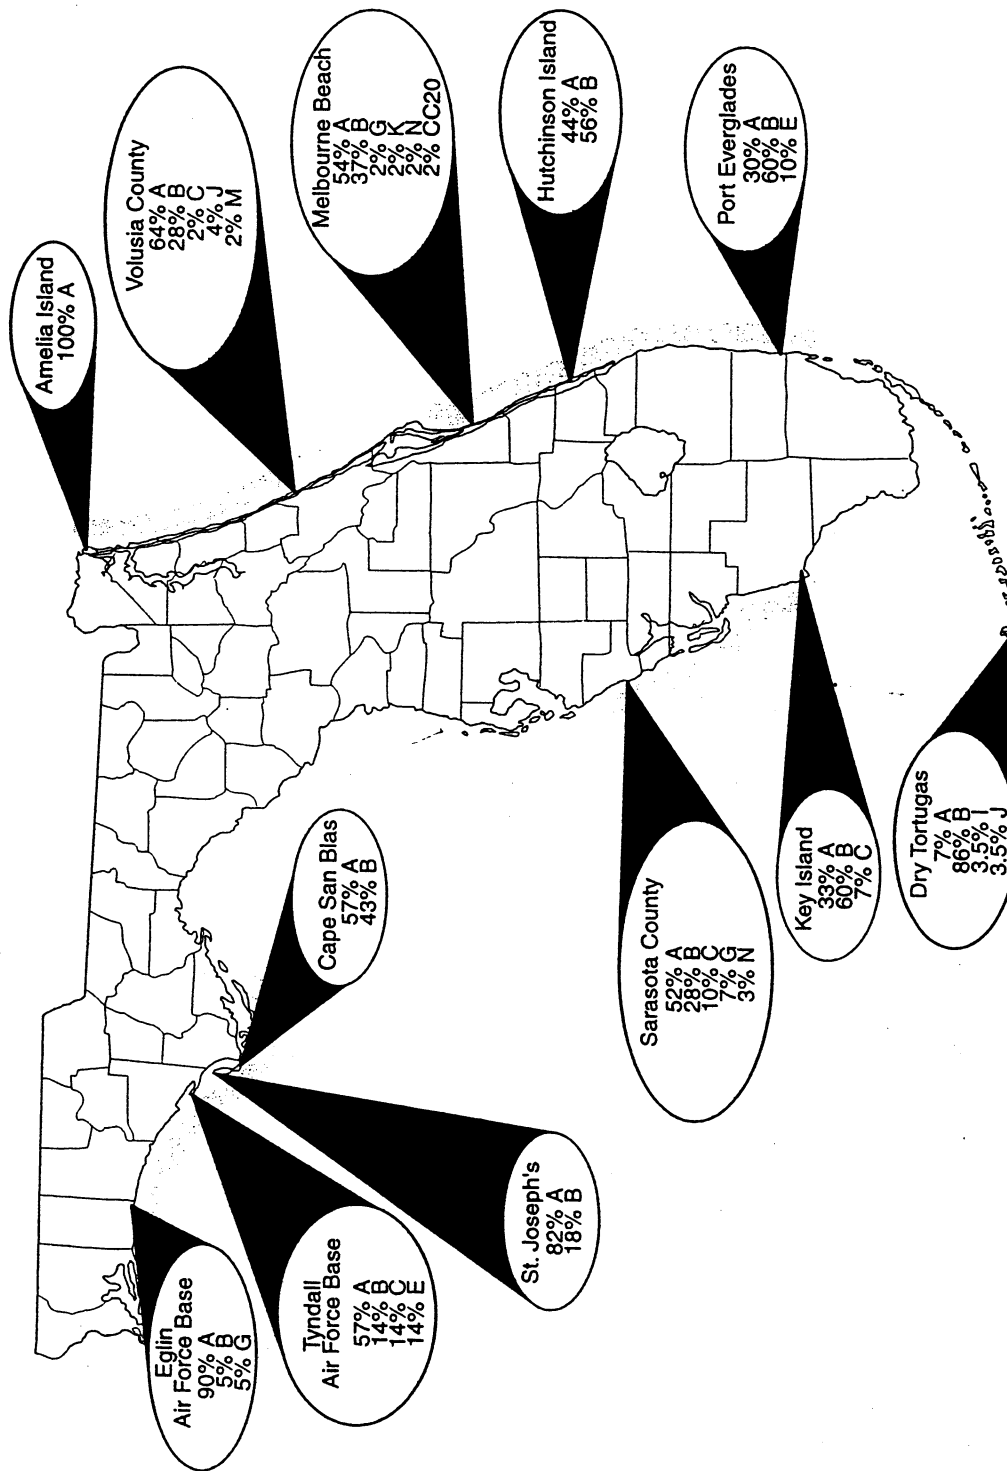

Figure 2. Mitochondrial control region haplotype frequencies for loggerhead turtles from twelve nesting beaches in Florida. Dark borders indicate the four biogeographic regions.

Chi-square analysis of overall haplotype frequencies showed highly significant population differentiation ($\chi^2 = 183.1$, $P < 0.005$) among the 12 nesting locations identified in Table 1. Pairwise comparisons between the four zones were significant (all $P < 0.008$), with the exception of the two most distant zones (NE and NW, see below). Comparisons between adjacent nesting sites were not significant except for the Dry Tortugas versus the adjacent mainland localities (Key Island and Port Everglades). Chi-square analysis of haplotype frequencies for 66 pairwise comparisons yielded significant differences in 23 cases (Table 2). Migration estimates between sample sites ranged from $N_m = 0.07$ to infinity (Table 2).

In the AMOVA comparison of sample sites (without regard to management zones), 29.8% of haplotypic diversity was distributed among nesting beaches, a value that is highly significant ($P < 0.001$). Hierarchical analysis of populations partitioned among zones revealed that 68.4% of haplotypic diversity was within nesting sites, 15.8% was distributed among populations within the four zones, and 15.8% was distributed among the zones (Table 3, comparison F). The partitions within and between populations are significant (AMOVA: $\Phi_{ST} = 0.316$, $P < 0.001$; $\Phi_{SC} = 0.188$, $P < 0.001$), but the variation between zones does not depart significantly from a random distribution ($\Phi_{CT} = 0.158$, $P = 0.179$). However, when we group the two southern regions (SE and SW) all the Φ values are significant (Table 3, comparison I).

Table 2. Above diagonal: pairwise haplotype frequency comparisons based on χ^2 statistics, using the Monte Carlo procedure. Numbers in parentheses indicate P -values for each comparison (significant values in bold). Below diagonal: migration rates based on Φ_{ST} estimator.

Populations	AI	VC	MB	HI	DT	PE	KI	SC	CSB	SJ	TAFB	EAFB

Table 3. AMOVA analyses for loggerhead populations of Florida to test for the geographic grouping that best explains the distribution of genetic diversity. Variance components are among populations (AP, where populations are individual nesting beaches), among groups (AG, where groups are biogeographic zones), among populations within groups (AP/WG) and within populations (WP). This table includes nine tests. Test of grouping A is within and among the 12 nesting beaches, Test of grouping B is within and among biogeographic zones NE, NW, SE, SW including the Dry Tortugas, Test of grouping C is within and among the four biogeographic zones with the Dry Tortugas as a separate category, Test of grouping D is within and among biogeographic zones and the Dry Tortugas combining SE and SW into a single "S" category, Test of grouping E is within and among biogeographic zones with Dry Tortugas included in S, Test F is a three-tiered analysis of variation within biogeographic zones between biogeographic zones and overall using the same groupings as B, Test G is a three-tiered test of grouping C, Test H is a three-tiered test of grouping E, and Test I is a three tiered test of grouping D.

Discussion

Populations of *Caretta caretta* are believed to be declining worldwide (Dodd 1988) such that Florida is an important reservoir of Atlantic nesting effort. To make informed management decisions about this species, geographic delineation of reproductive units is necessary. Loggerhead rookeries are spatially structured along matriline, due to female nest site fidelity, and this indicates demographic autonomy among nesting colonies (Aulsebrook 2000), regardless of the level of gene flow mediated by males. Therefore management units are defined by female nest site fidelity.

Analysis of mtDNA variance within and among populations reveals high levels of genetic partitioning. Over the entire state of Florida, nearly 30% of the total molecular variance was a result of variation among the twelve sampled nesting beaches ($\Phi_{ST} = 0.298$, $P < 0.001$) (Table 3). This value indicates strong population structure across Florida. However, the results from the chi-square analysis revealed there were no statistically significant differences between most adjacent populations.

Chi-square analysis also revealed no statistically significant differences between many distant populations. Migration estimates of $N_m < 4$ generally indicate that gene flow is too low to homogenize populations (Baker et al. 1983). By this criterion, 33 of 66 N_m pairwise estimates fell below the critical threshold (Table 3). Of the remaining 33 estimates ($N_m > 4$), 15 involve comparisons from opposite sides of the peninsula. The most extreme example is Amelia Island and Eglin Air Force Base, which are separated by over 1600 km of coastline.

How can we reconcile the strong overall population structure with the apparent genetic homogeneity of widely separated locations? Some long-term tagging studies have shown that there is occasional movement between nesting beaches (Bjorndal et al. 1983). Long distance relocations of nesting females could explain the high migration estimates between populations on opposite sides of the peninsula. However, most documented relocation events occur between adjacent nesting beaches involving a few tens of km, with more distant relocations occurring much less frequently (Richardson 1982).

Given the pattern of strong population structure revealed by Φ - statistics, and considering the life history characteristics of loggerhead turtles, a second explanation bears consideration. The similarity of the haplotype distributions between widely separated nesting beaches may be a remnant of historical lineage sorting, rather than an indication of present day migration. During the Wisconsin glaciation 24,000-10,000 years ago, loggerheads may have nested in south Florida but almost certainly not through the remainder of the current nesting range in Florida (see Hedgpeth 1954). Loggerheads require sand temperature of at least 25° C to nest (Dodd 1988); therefore the majority of the Florida peninsula has been amenable to nesting for less than 10,000 years. After the Wisconsin glaciation, loggerhead turtles evidently colonized up the coasts of Florida but have not had sufficient time to differentiate into highly isolated nesting colonies. Hence the observed population structure is shallow (in an evolutionary framework), encompassing less than 600 loggerhead generations. Considered in this historical context, the similarity of widely

separated locations is very likely a result of genetic drift during colonization northward from an ancestral population to the south.

Encalada et al. (1998) hypothesized that the break between populations on the Atlantic coast would occur somewhere between Amelia Island and Cape Canaveral, the location of a widely recognized biogeographic break between tropical and warm-temperate biota (Avice 1992). Volusia County nesting beaches lie within this region, and biogeographic considerations would indicate that they are affiliated with the nesting groups to the north. However the corresponding haplotype distribution is not easily affiliated with populations to the north or south. Chi-square analysis indicates that Amelia Island (to the north) and Volusia County are not differentiated ($P=0.25$), but this could be due to the low sample size from Amelia Island ($n=12$). When Amelia Island samples are grouped with the samples from adjacent Georgia barrier islands to the north (as suggested by Encalada et al. 1998) Volusia County is significantly different ($P<0.01$, data not shown). Volusia was not statistically differentiated from Melbourne Beach to the south ($P=0.16$), but this region has intermediate haplotype frequencies and may not belong to either the Amelia Island or Melbourne management units. In contrast, the Dry Tortugas is a highly distinct population, as indicated by significant χ^2 values in all pairwise comparisons with no migration estimates greater than $Nm=0.74$.

Based on the overall pattern of mtDNA distributions in Florida, we did not find differentiation on a scale of tens of km. We begin to find differences in comparisons across distances greater than 100 km. Tag returns are consistent

with this scale for management units; Richardson (1982) reports 20% nesting crossover between adjacent barrier islands in Georgia but only a 2-4% crossover involving more distant barrier islands along the Georgia coast. Based on these findings we conclude that natal homing occurs with the precision of tens of km. As a first approximation for defining management units, we suggest a scale of 100 km between discontinuous nesting habitats. In terms of Florida management units the SE and SW regions are not significantly different and perhaps should be combined into a single unit. The revised three regions (NE, S, and NW) plus the Dry Tortugas constitute management units that would protect the majority of genetic diversity indicated by mtDNA surveys.

Genetic diversity in mtDNA should not be the sole criterion for defining management units; demographic trends have to be taken into account, as well as the risk of extirpation for individual areas. For example, the Dry Tortugas is already protected as a National Park while other areas (such as Volusia County, which includes the tourist resort of Daytona Beach) are highly susceptible to human impacts that may be detrimental to sea turtle survival.

CHAPTER 3
MIGRATORY BEHAVIOR AND SITE FIDELITY IN MALE LOGGERHEAD
TURTLES (*CARETTA CARETTA*) IN THE NORTHWEST ATLANTIC USING
NUCLEAR DNA MARKERS

Introduction

Complex animal behaviors such as sex-biased dispersal or philopatry may be revealed by multi-locus population genetic studies. For example, population structure based on mitochondrial markers may differ from the structure defined using nuclear markers, due to the different inheritance mechanisms of these two genomes (Karl and Avise 1992). Mitochondrial DNA (mtDNA) is maternally inherited (passed from mother to offspring) without recombination, while nuclear DNA (nDNA) is biparentally inherited and undergoes recombination. Discordance between population structure detected with mtDNA and nDNA assays is indicative of sex-specific dispersal, as has been demonstrated in marine mammals, e.g. humpback whales (Baker et al. 1998). However, the unusual life history of marine turtles may provide the starkest examples: cases in which female matrilineages are highly structured and nuclear lineages have no population structure.

The loggerhead turtle (*Caretta caretta*) is distributed worldwide, inhabiting coastal temperate, tropical, and subtropical waters of the Atlantic, Indian and Pacific oceans. Females nest primarily on warm temperate beaches and after a 50-60 day incubation, hatchlings enter the surf to begin a pelagic phase where

they drift passively in ocean currents for five or more years (Carr 1986, Bjorndal et al. 2000). Advanced juveniles (or subadults) leave the pelagic habitat and recruit to shallow coastal feeding grounds. Upon reaching sexual maturity at an estimated 20-30+ years of age (Bjorndal et al. 2000, Klinger and Musick 1995), adult loggerheads leave the foraging grounds and travel tens to thousands of kilometers to mating and nesting grounds. Results from mark and recapture studies indicate that the majority of females return to the same nesting beach for subsequent nesting efforts (Carr 1986) and both sexes return to the same feeding grounds after reproductive migrations (Limpus et al. 1992).

Molecular techniques have enabled researchers to elucidate life history characteristics of marine turtles that would have taken decades of field studies, if they could be done at all. Surveys of the maternally inherited mtDNA genome have demonstrated natal homing in several sea turtle species, including green (*Chelonia mydas*; Bowen et al., 1992, Norman et al., 1994, Encalada et al., 1996), hawksbill (*Eretmochelys imbricata*; Bass et al. 1996), leatherback (*Dermochelys coriacea*; Dutton et al., 1999) and loggerhead turtles (Bowen et al., 1993, Francisco et al., submitted). Foraging ground studies utilizing mtDNA have linked adult and juvenile turtles to their corresponding rookeries (Broderick et al., 1994, Bowen et al., 1996, Lahanas et al., 1998) and have documented developmental migrations that span the Atlantic and Pacific oceans (Bowen et al., 1995, Bolten et al., 1998).

These mtDNA studies have been instructive, but they pertain predominantly to the female (egg-producing) lineages. Informed management

requires knowledge of male dispersal and philopatry as well. Specifically, wildlife managers need to know the migratory behavior of males and what effects their behavior has on the overall population structure. A few studies have examined biparentally inherited nuclear DNA (nDNA) loci in sea turtles. Peare and Parker (1996) analyzed minisatellite DNA in nesting green turtles and found genetic structure on the scale of a few kms in Tortuguero, Costa Rica but not in Melbourne Beach, Florida. Although this study looked at nDNA, the goal was to investigate the precision of female philopatry. Schroth et al. (1996) compared mtDNA and RAPD (random amplified polymorphic DNA) profiles in nesting loggerheads from the eastern Mediterranean and found that male-mediated gene flow was insufficient to prevent genetic subdivisions among neighboring rookeries. Karl et al. (1992) surveyed anonymous nDNA loci and demonstrated that male green turtles might provide an occasional avenue of gene flow between nesting colonies. Only one study to date has examined male-mediated gene flow using microsatellites; Fitzsimmons et al. (1997b) surveyed Australian green turtles and found that widely separated nesting aggregates were genetically distinct populations, although low levels of gene flow were detected. An interesting exception involved two nesting populations that overlap on migratory corridors or feeding grounds. Nuclear gene flow was found to be extensive between these two locations, despite a nearly fixed difference in mtDNA haplotypes (Fitzsimmons et al. 1997b).

Microsatellite DNA assays are generally considered to be the most sensitive population genetic marker for detecting fine scale population structure

(Goldstein and Pollack 1997). Microsatellites are preferred over RAPDs because each set of primers amplifies a single locus that contains a simple repeat motif. Variation in the number of repeats (such as CA7 or CA9) is responsible for the observed allelic diversity. The popularity of these genetic markers led to the development of statistical methods based on explicit models of microsatellite evolution (Goldstein et al., 1995, Slatkin et al., 1995).

Our analyses of loggerhead microsatellite loci allows for a comparison to studies using mtDNA alone and therefore an elucidation of the degree of male-mediated gene flow among nesting populations. Analysis of nuclear DNA can also reveal information on stock structure, effective population size, levels of inbreeding within small nesting populations, and can prevent some common pitfalls in stock definition (Bowen, 1997). This type of information is important for the resolution of management units and can greatly enhance the scientific foundations of recovery plans.

Materials and Methods

Sample Collection

We obtained 462 *Caretta caretta* specimens from 22 sites throughout the southeast U.S. and two additional sites in Brazil between 1995 and 1999 (Fig. 1). Tissue from moribund hatchlings, embryos and skin biopsy punches were placed in 15 ml of a saturated salt buffer (Amos and Hoezel, 1991), and stored at room temperature. Blood samples were obtained from the dorsal cervical sinus of nesting females following the procedure of Owens and Ruiz (1980) and were

stored in a 9:1 lysis buffer-to-blood ratio at room temperature (Fitzsimmons et al. 1999). Whole genomic DNA was isolated according to Hillis et al (1996) using a standard phenol chloroform extraction and ethanol precipitation.

Microsatellite Library

Microsatellite library construction was accomplished using the strategy of Kandpal et al. (1994). Genomic DNA from two different locations were combined, digested with Sau3AI, and fractionated on a 1.2% agarose gel. The 400- to 1500 bp region was excised from the gel, and purified using the QIAquick Gel Extraction Kit (Qiagen, Valencia, CA). The purified DNA was ligated to Sau3AI linkers using T4DNA ligase. Excess linkers were removed by gel electrophoresis, and the 400-1500 bp region was recovered using the QIAquick Gel Extraction Kit. One microgram of ligated DNA was denatured and then hybridized in solution to a biotinylated probe (5'-(CA₁₅TATAAGATA-biotin-3'). The hybridized fragments were captured using VECTREX Avidin D (Vector Laboratories, Burlingame, CA) following the manufacturers instructions.

Enriched DNA fragments were amplified by polymerase chain reaction (PCR) with Sau-L-A primer (5'-GCGGTACCCGGGAAGCTTGG-3'). PCR parameters (1.5 mM MgCl₂, 100 uM dNTPs each, 0.5 uM primer, 2.5 U Taq in a 50 uL rxn 94 °C for 3 min initial denaturation, (94 °C 1 min, 68 °C 1 min, 72 °C 2 min) 25 cycles, 72 °C for 10 min final amplification). The PCR product was ligated to the pCR2.1 vector from the TOPO-TA cloning kit (Invitrogen, Carlsbad, CA), transformed into competent *E. coli* INValphaF cells and plated onto LB-ampicillin (50 ug/mL) agar plates.

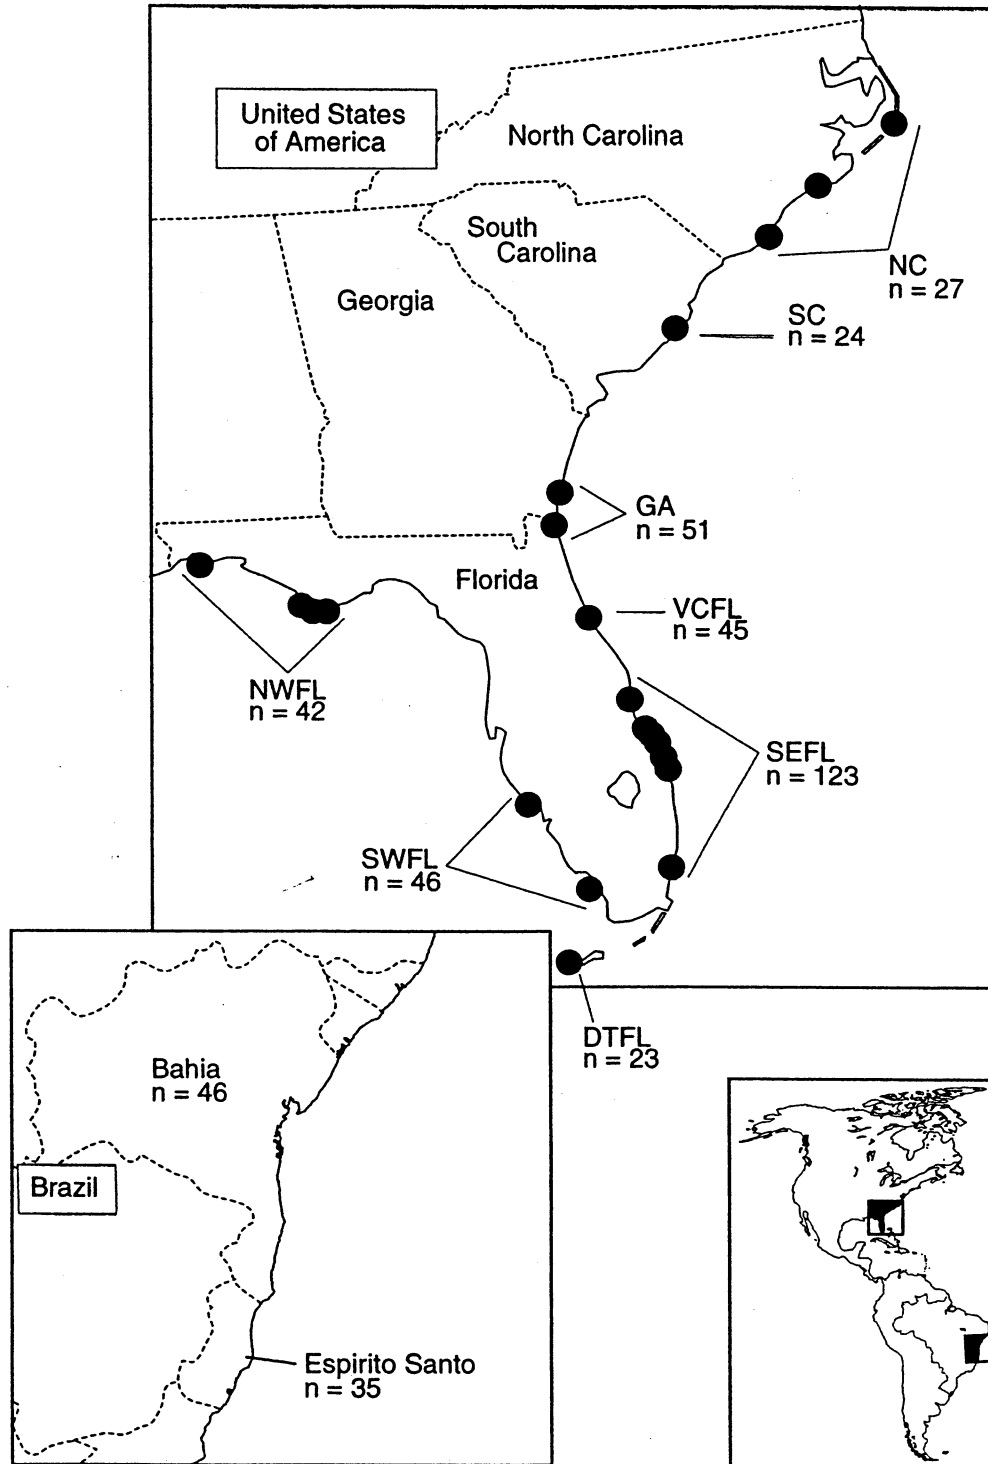

Figure 3. Collections sites and analysis groupings for *C. caretta* samples from the southeast U.S. and Brazil.

Bacterial clones were screened by direct colony lifts using nylon hybridization membranes (Micron Separations, Inc, Westboro, MA), hybridized with a (CA)_n probe (Lifecodes Corp, Stamford, CT), and developed with Lumi-phos 480 (modified dioxtanes). The membranes were exposed to x-ray film that was visually inspected for microsatellite positive clones. Positive clones were cultured overnight in 3 mL of LB-Amp (Luria broth with 100 uL/mL Ampicillin). The cultured cells were pelleted and plasmids purified using the Qiagen Miniprep Kit. A dot blot was performed on each sample to confirm the presence of CA repeats.

Plasmids positive for CA repeats were sequenced by the DNA Sequencing Core at the University of Florida. Oligonucleotide primers were designed in the regions flanking the repeats using Oligo Primer Analysis software (Molecular Biology Insights, Inc., Cascade, CO).

Microsatellite Amplification

Four microsatellite loci (dinucleotide repeats) previously shown to be polymorphic in loggerheads plus one locus developed for this project were used for population analysis: CC141 and CC7 (Fitzsimmons 1996, 1998); Ccar176 (Moore 2000); DC107 (Dutton, pers comm.); and CCM2 (this study). One primer from each locus was fluorescently labeled with either 6-Fam or Tet (CyberSyn, Lenni, PA). The loci were amplified in 10 uL reactions containing 25-50 ng of DNA, 1x Promega PCR buffer, 0.2 mM each dNTP, 0.375 - 1.125 mM MgCl₂, 0.4 U Promega Taq, and 8 pmol of each primer. The cycling parameters used were: one cycle of denaturation at 93 °C for 3 min, followed by 6 cycles of denaturation

at 92 °C for 30s, annealing at 60 °C (Ccar176), 58 °C (CCM2), 56 °C (CC141, CC7), 55 °C (DC107) for 55s, and extension at 72 °C for 1 min 25 s, followed by 30 cycles of denaturation at 89 °C for 30s, annealing at 2 °C lower than previous cycle for that primer pair, and extension at 72 °C for 1 min 25 s, followed by a final extension at 72 °C for 10 min. PCR products were analyzed either by the Iowa State University Sequencing Facility with an ABI 377 or on an ABI 310 automated sequencer (Applied Biosystems Inc., Foster City, CA) in the Dept. of Fisheries and Aquatic Sciences at the University of Florida.

Data Analysis

Allele designations were assigned using Genescan Analysis software (Perkin-Elmer Corp., Foster City, CA). Population subdivisions were determined a priori based on previous mtDNA studies. The localities were initially partitioned into ten groups: 1) North Carolina (n=27); 2) South Carolina (n=24); 3) Georgia plus adjacent Amelia Island, FL (n=51); 4) Volusia County (n=45); 5) Southeast Florida (SEFL; n=123) from Cape Canaveral to Port Everglades; 6) Dry Tortugas, Florida (DTFL; n=23); 7) Southwest Florida (SWFL; n=46) from the Everglades to Tampa Bay; 8) Northwest Florida (NWFL; n=42) the Panhandle; 9) Bahia, Brazil (n=46); 10) Espirito Santo, Brazil (n=35). Since we found no significant differences between northern and southern sample sites in Brazil (separated by no more than 1000 kms) they were subsequently grouped together for all statistical tests.

Tests for departure from Hardy-Weinberg equilibrium (HWE), differences in allelic counts among localities, and pairwise tests for population differentiation

using allele frequencies were conducted using GENEPOP version 3.1 (Raymond and Rousset 1995). P-values were calculated with a Markov chain-randomization (Guo and Thompson 1992). Fisher's method, which assumes statistical independence across loci, was used to combine test results for allelic counts among localities for all five loci (Raymond and Rousset 1995).

Estimates of population structure were made using both the infinite-alleles (IAM) and the stepwise mutation (SMM) evolutionary models. The extent of population subdivision under the IAM was examined with an analysis of molecular variance (AMOVA) using ARLEQUIN ver 2.0 (Schneider et al. 2000). This program package calculates F-statistics (Wright 1965) utilizing the methodology of Weir and Cockerham (1984). F statistics are used to partition the genetic variation within populations (F_{IS}) and between populations (F_{ST}) (populations have been determined a priori based on geographic or other criteria). Slatkin's (1995) R_{ST} was used to quantify genetic differentiation under the SMM. RSTCALC (Goodman 1997) was used to calculate p, an estimator of R_{ST} that takes into account differences in variation among loci and differences in sample size among populations. The significance of these estimates was evaluated by describing the null distribution of pairwise F_{ST} or pairwise p-values (R_{ST}) under the assumption of panmixia by 1000 permutations of genotypes between populations, or genotypes across population strata.

Results

In screening for new microsatellite loci, a total of 25 positive clones were sequenced. Of these 25, three had no microsatellite array, 12 did not contain enough flanking region for primer design, and primers were designed for the remaining ten. Four of the loci were monomorphic, and five of the primer pairs did not amplify reliably despite repeated optimization attempts (Table 1). The remaining locus was used in this study, in addition to the four loci characterized in previous studies.

High levels of polymorphism were observed at all five loci (Table 2). The number of distinct alleles observed per locus ranged from 10 for CCM2 to 29 for Ccar176 with an average of 16.8. Gene diversity (H_e) ranged from 74.5% (CCM2) to 86.5% (CC141) and averaged 79.6%. The observed heterozygosities (H_o) were also high with values greater than 72% at all five loci (Table 2). In all cases alleles varied by increments of 2bp, consistent with characterization of a CA motif.

Table 4. Primer sequences, annealing temperatures (T_a), size of amplified product and observed heterozygosity (H_o) for microsatellite primer pairs developed.

Table 5 *Caretta caretta*. Summary statistics for five microsatellite loci evaluated [product size in basepairs, number of alleles (k), gene diversity (aka expected heterozygosity, H_e), and observed heterozygosity (H_o)].

Locus	Product size (bp)	k	H_e	H_o
DC107	158-186	11	0.7742	0.7834
CCM2	169-195	10	0.7452	0.7208
Ccar176	117-181	29	0.8134	0.7930
CC141	186-220	16	0.8651	0.8004
CC7	209-247	18	0.7802	0.7473
Mean		16.8	0.7956	0.7690

Allelic counts were similar at all localities (Fisher's method $\chi^2 = 96.30$, df = 90, $P = 0.31$). The size-frequency distributions of microsatellite alleles varied among the nine populations (Figs. 2-6). For loci Ccar176, CC141 and CC7 the allelic distributions were skewed to the left (Figs. 4-6), and locus DC107 was skewed slightly to the right (Fig. 2). Allele distributions for the Brazilian population showed reduced diversity (relative to the southeast U.S.) with a single allele occurring at over 50% frequency at three of the five loci [allele 185 at locus CCM2 (Fig. 3), allele 192 at locus CC141 (Fig. 5), and allele 219 at locus CC7 (Fig. 6)].

In tests of Hardy Weinberg equilibrium three of 45 population/locus combinations (Volusia County, FL/CC7, $P = 0.02$, Dry Tortugas, FL/CC141, $P = 0.02$, and Northwest FL/CC141, $P = 0.03$) deviated significantly from expected values (95% confidence level)(Table 3). In all three cases this indicated a lower than expected heterozygosity. The departure from Hardy-Weinberg equilibrium was not significant at the table wide level when Fisher's method was used to combine the 45 independent tests ($P = 0.31$).

Pairwise tests for genetic differentiation using allele frequencies show that the Brazilian turtles are genetically distinct from all other populations surveyed here (Table 5). Considering just the southeast U.S., genetic differentiation was observed between the Dry Tortugas and three other locations at locus CC141 (Table 5). In comparing Georgia to other locations, nine of 35 pairwise tests showed significant genetic differentiation (Table 5).

Pairwise F_{ST} values (the proportion of diversity among populations) were calculated and compared to R_{ST} , an analogue of F_{ST} , to estimate levels of genetic

differentiation for microsatellite loci (Table 6). Georgia had significant F_{ST} estimates in six out of eight comparisons (the exceptions being North Carolina and the Dry Tortugas) while the only significant R_{ST} values were in comparisons of Brazil vs. the southeast U.S. locations (Table 6). However, the R_{ST} values for Brazil vs. North Carolina and Brazil vs. the Dry Tortugas were not significant ($p=0.46$ and $p=0.095$, respectively). The R_{ST} estimate for overall comparisons was lower than the corresponding F_{ST} estimate (0.0057 and 0.0189, respectively). Estimates of F_{ST} and R_{ST} for each locus at all localities ranged from 0.004 to 0.0372 and -0.0063 to 0.0362 respectively (Table 4). Single locus F_{ST} estimates for three loci (CCM2, CC141, CC7) were significantly greater than zero as was the combined estimate for all loci ($F_{ST} = 0.0189$) whereas only CC141 and CC7 had significant single locus R_{ST} estimates and the combined estimate was significant ($R_{ST} = 0.0057$)(Table 4).

Table 9. *Caretta caretta*. F_{ST} (below diagonal) and Slatkin's analogous R_{ST} (above diagonal) between all pairs of populations. **, $P < 0.05$ and $P < 0.001$ respectively calculated from 1000 random permutations.

Discussion

Surveys of nesting loggerhead turtles with mtDNA have shown population structuring, consistent with female natal homing (Bowen and Karl 1996).

Francisco et al. (submitted) found high levels of population structure over the state of Florida based on mtDNA haplotypes ($\Phi_{ST} = 0.298$). However, the same populations have much less population structuring at five nuclear loci. When five Florida populations along with North Carolina, South Carolina, Georgia and Brazil were analyzed using microsatellites, the comparable population statistics were more than an order of magnitude lower ($F_{ST} = 0.0189$). Previous studies have reported incongruence between mitochondrial and nuclear based variation, e.g. in trout (Bernatchez and Osinov 1995), the African elephant (Nyakaana and Arctander 1999) and Dall's porpoise (Escorza-Trevino and Dizon 2000). These studies explained the apparent discrepancies as differences in the inheritance dynamics as well as different modes and rates of mutation between the two types of genetic markers.

The discrepancy between mtDNA and microsatellite data indicates that male loggerheads provide an avenue for gene flow among matrilineally-structured nesting colonies. To reconcile the mtDNA and nDNA data, three classes of explanations bear consideration. First, perhaps male loggerheads are not philopatric and they migrate to non-natal breeding aggregations.

Fitzsimmons et al. (1997a) sampled male green turtles on courtship areas and compared the mtDNA frequencies to those of the nesting females in those areas. They found that the haplotype frequencies were comparable between the sexes

indicating that males were returning to the vicinity of their natal site to breed. Since the life history characteristics of these two species are similar we suspect that these findings may also pertain to loggerheads, and provisionally discount the hypothesis that males are not philopatric.

The second possibility is that males are philopatric to natal sites for breeding, but they also mate opportunistically, copulating with receptive females on feeding grounds or in migratory corridors (Bowen 1997). Male Australian green turtles were found to migrate more frequently to breeding grounds than females and had a tendency to inhabit foraging grounds closer to the nesting habitat (Fitzsimmons et al. 1997b). Females may be intercepted by males during reproductive migrations, especially if they pass through nonnatal courting areas.

A third alternative is that only a percentage of males are philopatric. Genetic studies of weakfish (an estuarine-spawning marine fish) utilizing allozymes and mtDNA found no genetic differentiation among spawning populations (Crawford et al., 1989, Graves et al., 1992). However, Thorrold et al. (2001) used geochemical signatures in otoliths and found that spawning site fidelity ranged from 60 to 81%. The majority of male loggerheads may be philopatric to natal sites, but this fidelity may not be detected in nDNA assays as it would only take a few strays to homogenize populations.

Results from pairwise tests of allelic frequencies (Table 5) and pairwise F_{ST} 's (but not R_{ST})(Table 6) revealed significant differences between Georgia and most other southeast U.S. populations. These results are intriguing because Georgia is not obviously more isolated or distant than the other U.S. populations.

In principle it is possible that Georgia turtles are resident year-round, although adults are only documented to occur in Georgia's coastal waters from May to October with any regularity (Ruckdeschel et al. 2000). Another alternative is that Georgia turtles have different migratory routes than other turtles and thereby avoid inter-rookery gene flow. This could be tested with satellite transmitters. A third possibility, prompted by the R_{ST} results (Table 6), is that the significant F_{ST} values do not reflect a biological phenomenon, but are an artifact of our analysis. However, spurious values would be expected to be scattered throughout the data set, not aligned with comparisons of Georgia versus elsewhere. The explanation for the Georgia findings is not clear at this time.

The difference between Brazilian and U.S. loggerheads represents the deepest genetic partition observed in our study. Analysis of mtDNA revealed no shared haplotypes between the two countries (Encalada et al. 1998, unpub data) and analysis of nuclear loci found significant allele frequency shifts. These differences highlight a cryptic aspect of the life history of loggerhead turtles. Juvenile loggerheads have been shown to cross both the North Atlantic and North Pacific oceans during developmental migrations (Bolton et al., 1998, Bowen et al., 1995), but they may only rarely cross between northern and southern hemispheres (Bowen et al. 1995). The significant population differentiation between northern and southern ocean basins in the Atlantic indicates that reproductive migrations do not span the equator and there do not appear to be avenues for routine gene flow between these locations.

CHAPTER 4 CONCLUSIONS

Conservation Implications

Loggerhead turtles have complex population structure. Population genetic theory, particularly the rules of inheritance, predict that such an outcome is possible (Avice 2000). The conservation ramifications are incompletely understood, but two conclusions are possible at this time: first, the occurrence of male-mediated gene flow does not change the status of rookeries as distinct management units (MUs). MU's as defined by Moritz (1994) are 'populations with significant divergence of allele frequencies at nuclear or mitochondrial loci'. mtDNA studies have shown that nesting populations have significant haplotype frequency differences and, regardless of the level of philopatry in males, the female (egg-laying) lineages are clustered by nesting beach fidelity. Because maternally inherited mtDNA is an indicator of historical female reproductive success, as noted by Avice (1995, 2000), the strong matrilineal population structure implies independent recruitment and demographic autonomy. Second, the interconnectivity of nesting populations in the southeast U.S. through male-mediated gene flow has some positive aspects in terms of conservation and management. Many of the nesting populations in the southeast U.S. are relatively small, especially in the Florida panhandle, Georgia, South Carolina and North Carolina. For these nesting aggregates, male-mediated gene flow

indicates that reduced genetic diversity in small populations is not a compelling issue. In typical small, isolated populations, genetic diversity is quickly lost by bottlenecks, low effective population size, and genetic drift. Loss of genetic diversity may retard a population's response to challenges such as disease, habitat degradation, climate changes or other perturbations, consequently the population is more susceptible to extinction. Small loggerhead nesting aggregates may not be susceptible to these problems as male-mediated gene flow can maintain high levels of nuclear DNA diversity in small nesting aggregates.

Finally, these findings indicate that nesting populations of the northwest Atlantic are not evolutionarily significant units (ESU's) defined as 'reciprocally monophyletic for mtDNA alleles and showing significant divergence of allele frequencies at nuclear loci' (Moritz 1994). Under this definition it may be possible to define ESU's as clusters of rookeries within ocean basins but certainly not at the scale of individual nesting aggregations. An exception to this generalization may be when only one nesting aggregate occurs in an ocean basin, in which case the ESU may be a single population.

Prospectus

Several research challenges lie ahead. First, it is desirable to test the alternatives we used to explain male-mediated gene flow. This can be initiated with mtDNA and microsatellite surveys of courting grounds, to assess the degree of male philopatry. Additional studies of the Georgia rookery are necessary to determine if some special life history attribute underlies the finding of genetic

· distinctiveness. Finally, satellite telemetry may reveal the extent of overlap and contact between reproductive populations on foraging grounds. An appropriate balance of field and lab studies will be necessary to illuminate the reproductive behaviors of these enigmatic marine reptiles.
